Continuous chemical redistribution following amorphous-to-crystalline structural ordering in a Zr-Cu-Al bulk metallic glass

Thursday, 25 November 2021 18:41 (1 minute)

Bulk metallic glasses (BMGs) are thermodynamically metastable. As such, crystallization occurs when a BMG is thermally annealed at a temperature above the glass transition temperature. While extensive studies have been performed on the crystallization kinetics of BMGs, most of them have focused on the amorphous-to-crystalline structural ordering, and little attention has been paid to chemical distribution and its relationship with the structural ordering during the crystallization process. In this paper, a new approach, with simultaneous differential scanning calorimetry (DSC) and small angle neutron scattering (SANS) measurements, was applied to study in situ the crystallization of a $\text{Zr}_{45.5}\text{Cu}_{45.5}\text{Al}_9$ BMG upon isothermal annealing at a temperature in the supercooled liquid region. Quantitative analysis of the DSC and SANS data showed that the structural evolution during isothermal annealing could be classified into three stages: (I) incubation; (II) amorphous-to-crystalline structural ordering; (III) continuous chemical redistribution. This finding was validated by composition analysis with atom probe tomography (APT), which further identified a transition region formed by expelling Al into the matrix. The transition region, with a composition of $(\text{Cu,Al})_{50}\text{Zr}_{50}$, served as an intermediate step facilitating the formation of a thermodynamically stable crystalline phase with a composition of $(\text{Cu,Al})_{10}\text{Zr}_{7}$.

Presenter Gender

Woman

Do you wish to take part in the Student Poster Slam

Condition of submission

Students Only - Are you interested in AINSE student funding

Level of Expertise

Early Career <5 Years

Pronouns

She/Her

Which facility did you use for your research

Australian Centre for Neutron Scattering
