

Microstructural design of Ni-base superalloys by hot isostatic pressing

Wednesday, 6 December 2017 16:25 (25 minutes)

Single crystal Ni-base Superalloys (SXs), used as blade materials, operate at temperatures close to their melting point and have to withstand mechanical and chemical degradation. Casting and extensive solution heat-treatments of such blades introduce porosity, which can only be reduced by hot isostatic pressing (HIP). Recent developments of a HIP unit with a quenching possibility allow performing heat-treatments and eliminate porosity simultaneously. This work gives an overview about the opportunities that such a unique HIP offers for the solution heat-treatment of conventionally cast SXs or directionally solidified Ni-base superalloys fabricated by selective electron beam melting (SEBM).

The influence of temperature, pressure, and cooling method on the evolution of γ/γ' -morphology and on the pore shrinkage is investigated. The cooling method has a strong impact on the γ' -particle size and shape. Slow or natural cooling lead to coarse γ' -precipitate sizes. Quenching after solutioning at 100 MPa leads to a high number density of small γ' -particles, ideal for the subsequent formation of a fine and uniform γ/γ' -microstructure after ageing. Porosity reduction was most efficient at $T > T_{\text{solvus}}$. Based on these findings, first, an integrated solution and aging heat treatment for an as-cast SXs is implemented into the HIP unit. Second, short HIP treatments are applied on SEBM parts, generating promising and defect free microstructures. Finally, a HIP treatment is satisfactorily used to rejuvenate the γ/γ' -microstructure of SXs after creep degradation, re-establishing the γ/γ' -microstructure without recrystallization and closing all pores and creep cavities.
